ABSTRACT

Six years old, Spitz cross intact male dog was presented to the Ophthalmology unit, Department of Clinics, Madras Veterinary College Teaching Hospital with the history of wound on right eye with severe swelling on face and serosanguinous discharge for two days. Clinical examination revealed large ulceration, oedematous swelling of periorbital tissue. On thorough examination it was only upper eyelid with numerous live maggots. The palpebral conjunctiva and other ocular tissues were intact. After instillation of topical 4% Lignocaine, numerous live maggots were removed with forceps. Cleaning of wound was done with 0.5 % Povidone Iodine solution and Scavon (Himalaya®, Animal Health) ointment was applied for a week. Systemic antibiotics and anti-inflammatory were prescribed for 5 days. Swelling has reduced gradually and wound healing has occurred in two weeks.

Keywords: External Ophthalmomyiasis, Dog

INTRODUCTION

Ophthalmomyiasis is the infestation of the eye by dipterous fly larvae and it can be external or internal (anterior or posterior) (Esmeralda Delgado, 2012). Ophthalmomyiasis is divided into orbital, internal, and external, based on site of larval infestation (Sigauke, 2003). Orbital and internal ophthalmic myiasis is caused by larva with invading habits leading to blinding manifestations. External ophthalmic myiasis refers to superficial infestations of ocular tissue such as conjunctiva and eyelids (Ratnesh Ranjan and Ravi Jain, 2014). But external ophthalmomyiasis caused by invading larva can also result in serious complications such as corneal ulcer, iridocyclitis, globe invasion, endophthalmitis, and even blindness (Shankar et al., 2012). Topical anaesthetic was used to reduce the motility of larvae (Thakur et al., 2009).

CASES

Six years old, Spitz cross intact male was presented with wound on right upper eyelid with swelling on periorbital tissue and face, serosanguinous discharge (Figure 1). On clinical examination revealed external ophthalmomyiasis.

DISCUSSION
On the day of presentation, after topical 4% Lignocaine, numerous live maggots were removed. Wound was cleaned with 0.5% Povidone Iodine solution and Scavon (Himalaya®, Animal Health) ointment was applied and continued for a week. Ivermectin @ 400 µg/kg body weight was given subcutaneously. Systemic antibiotics Ceftriaxone @ 10 mg/kg body weight and Prednisolone @ 0.5 mg/kg body weight were given orally for 5 days. Swelling has reduced gradually and wound healing has occurred within two weeks of treatment. No complications were recorded (Figure 2 and Figure 3).
