ABSTRACT
Distributed computing systems (DCS) are of current interest due to the advancement of microprocessor technology and computers networks. It consists of multiple computing nodes that communicate with each other by message passing mechanism. Reliability and communication over distances are the main reasons for building the DCS. In distributed computing systems, partitioning of applications software in to modules and proper allocation of modules among processors are important factors for efficient utilization of resources. We consider the problem of m-modules and n-processors \((m \gg n)\). In this paper a mathematical model for finding optimal cost and optimal reliability to the problem is presented considering DCS with heterogeneous processors in such a way that the allocated load on each processor is balanced. The results obtained by the present model are compared with the recent models and compared results show that the model is very effective.

Keywords: Distributed Computing System, Module Allocation, Inter Module Communication, Reliability, Data Transfer Rate, Inter Processor Distance

INTRODUCTION
Improvements in device technology have allowed computer speed to increase by several orders of magnitude in recent decades. The computing capabilities demanded by a number of real world applications have increased at an even faster pace. The required processing power for these applications can’t be achieved with a single processor. One approach to this problem is to use distributed computing systems (DCS) that concurrently process an application program by employing multiple processors. In DCS homogeneous or heterogeneous processors are connected together through a communication network. Distributed computing provides the capability for the utilization of remote computing resources and allow for increased levels of flexibility, reliability and modularity. If DCS are properly designed and planned they can provide a more economical and reliable approach than that of centralized processing system.

A distributed computing system has attracted several researchers by posing several challenging problems. In a DCS the execution of a program may be distributed among several computing elements to reduce the overall system cost by taking advantage of heterogeneous computational capabilities and other resources within the system. Reliability is defined in terms of the time interval in contrast to an instance in time defined in availability. A highly reliable system is one that will continue working for a long period of time. The often advocated advantage of the DCS, in comparison to the centralized system, is the reliability due to the existence of multiple resources. However, only the multiple instances of resources cannot increase the reliability of the DCS, rather the various processes of the distributed operating system (viz. memory manager, task scheduler etc.) must be designed properly to increase the reliability by extracting the characteristic features of the DCS.

The module allocation in a distributed processing system finds extensive application in the faculties where large amount of data is to be processed in a short period of time or where real time computations are required. Meteorology, Cryptography, Image analysis, Signal processing, Solar and Radar surveillance simulation of VLSI circuits and industrial process monitoring are areas of such applications. These applications require not only very fast computation speeds but also different strategies involving distributed module allocation systems. In such applications the quality of the output is proportional to the
amount of real life computations. The main incentives for choosing DCS are higher throughput improved availability and better access to a widely communicated web of information. The increased commercialization of communication systems means that ensuring system reliability is of critical importance inherently. DCS is more complex, therefore, it is very difficult to predict the performance of DCS. Mathematical modelling is the tool which can play an important role to predict the performance of DCS. Therefore, there is an urgent need to develop a method for it.

The performance of DCS may suffer if the mapping of distributed applications to processors is not carefully implemented. In order to make best use of the resources, it becomes essential to maximize the overall through put by allocating the modules to processors in such a way that the allocated load on all the processors should be balanced and to minimize the inter module communication by assigning modules to same processor as much as possible. Which are both contrary to each other as an increase in the number of processors may actually decrease the total throughput of the system. This degradation effect is known as saturation effect, which occurs due to heavy communication traffic induced by data transfers between modules that reside on separate processors.

Allocation of modules in a DCS may be done by two ways: static allocation and dynamic allocation. In static allocation once a module is assigned to a processor, it remains there statically during the execution of a distributed program (Ghafoor and Yang, 1993; Towsley, 1986; Chu, 1969; Dessoukiu-El and Huna, 1980; Sinclayer, 1988; Richard et al., 1982; Lin, 2002; Baca, 1989; Fernández-Baca, 1989; Kumar, 2001; Kumar et al., 1995; Kumar et al., 1995; Peng et al., 1997; Sagar and Sarje, 1991; Singh et al., 1999; Srinivasan and Jha, 1999; Yadav and Kumar, 2002; Zahedi and Ashrafi, 1991; Yadav et al., 2011). While in dynamic allocation a module can be reassigned during program execution (Yadav et al., 2008; Bokhari, 1979). Several methods owing the use of integer programming (Ghafoor and Yang, 1993; Towsley, 1986; Chu, 1969; Dessoukiu-El and Huna, 1980), critical delay consideration (Sinclayer, 1988), branch and bound technique (Richard et al., 1982), reliability evaluation (Lin, 2002; Baca, 1989; Fernández-Baca, 1989; Kumar, 2001; Kumar et al., 1995; Kumar et al., 1995; Peng et al., 1997; Sagar and Sarje, 1991; Singh et al., 1999; Srinivasan and Jha, 1999; Yadav and Kumar, 2002; Zahedi and Ashrafi, 1991; Yadav et al., 2011) have been reported in the literature.

This paper deals with the module allocation problem having multiple objectives such as: minimization of system cost, maximization of system reliability and load balancing for proper utilization of the processor’s capacity. The model used the mathematical programming technique for allocations of modules statically considering the effect of inter processor distances. Several sets of input data are used to test the effectiveness and efficiency of model. It is found that the model is suitable for arbitrary number of processors with the random program structure.

The rest paper is organized as follows: Module assignment problem and definitions are defined first in section 2. In section 3, modules allocation model has been discussed. The Section 4 shows the experimental results in comparison to other scheduling methods and concludes the paper.

Module Assignment Problem and Definitions

The specific problem being addressed here is as follows:

We considered a distributed system consisting of a set P= {p_1, p_2, ..., p_n} of ‘n’ heterogeneous processing nodes (e.g. host computer complexes in a computer network, individual processors in a multiprocessing environment) and an application program consisting of a set M={M_1,M_2, ..., M_m} of ‘m’ communicating modules to be executed on these processing nodes.

An allocation of modules to processors is defined by a function A from the set M of modules to the set P of processors such that: A:M→P, where A(i)=j if module M_i is assigned to processor P_j, 1 ≤ i ≤ m , 1 ≤ j ≤ n. (I)

In general the objective of modules allocation is to find an optimal allocation A_o, which minimize the completion time of the program and optimize the system reliability by properly mapping the modules to the processors. In order to make the best use of the resources in a distributed computing system we would like to distribute the load on each processor in such a way that allocated load on the processors are balanced. The following terms, notations and assumptions will be used throughout the text.
System Cost Functions:

Execution cost (EC): The execution cost $e_{ij}$ ($1 \leq i \leq m, 1 \leq j \leq n$) of each module $M_i$ depends on the capability of the processor $P_j$ to which it is assigned and the work to be performed by each module. The execution cost of each module on all the processors is taken in the form of execution cost matrix, $ECM=\{e_{ij}\}$ of order $m \times n$. The execution cost of each processor for an allocation $A$, is calculated using equation (II) as:
\[
PEC = \sum_{1\leq i \leq m \atop i \in MS_j} e_{i,A(i)} \quad \text{where} \quad MS_j = \{i: A(i)=j, j=1,2,\ldots,n\} \quad \text{(II)}
\]

Overall execution cost of a given allocation $A$ is calculated as:
\[
EC(A) = \sum_{1\leq i \leq m \atop i \in MS_j} e_{i,A(i)}
\]

Inter module communication cost (IMCC):

In this paper, the matrix $DT=\{data_{i,j}\}$ of order $m \times m$ is used to represent the data communication between the modules during the execution, where $data_{i,j}$ is the amount of data required to be transmitted from module $M_i$ to module $M_j$. The data transfer rates, i.e. bandwidth size, (in bytes/seconds) between processors are stored in a matrix $DTR=\{r_{i,j}\}$ of size $n \times n$. The communication start-up costs of processors are given in an n-dimensional vector $L=\{L_i\}$. The IMCC between modules $M_i$ and $M_j$ is defined by:
\[
c_{i,j} = \begin{cases} 
\alpha + \frac{data_{i,j}}{\beta}, & \text{if } i \neq j \\
0, & \text{if } i = j 
\end{cases}
\]

Where ‘$\beta$’ is the average transfer rate among the processors in the processors domain, and ‘$\alpha$’ is the average communication start-up time. The communication between the modules are taken in form of inter module communication cost matrix, $IMCCM=\{c_{i,j}\}$ of order $m \times m$.

Let us denote $d_{x,y}$ the distance between the processors $P_x$ and $P_y$. The processors $P_x$ and $P_y$ are connected by a communication link say $L_{x,y}$. The inter-processor communication cost per unit of information transferred between two processors $P_x$ and $P_y$ increases linearly as the distances $d_{x,y}$ increases. To consider the impact of inter processor distance on the cost, we define a inter processor distance matrix $IPDM=\{d_{i,j}\}$.

Thus, if two interacting modules $M_i$ and $M_j$ are assigned to two different processors $P_i$ and $P_s$, respectively, then the two modules cause the inter-processor communication cost of $c_{i,j} \times d_{i,s}$. We assume that the communication cost between two modules assigned to the same processors is negligible, since all communication is through memory as opposed to an inter-processor link. The overall inter-module communication cost and inter-module communication cost for each processor for a given allocation $A$, are obtained by equations as:
\[
TCC(A) = \sum_{1\leq i \leq m \atop i \in MS_j \atop i \neq A(j)} c_{i,j} \times d_{A(i),A(j)}
\]
\[
IPCC(j) = \sum_{1\leq i \leq m \atop i \neq A(j)} c_{i,k} \times d_{A(i),A(k)}
\]

Total cost and response time of the System: The total cost, $TCOST(A)$ of the system for an allocation $A$ is computed as:
\[
TCOST(A) = EC(A) + TCC(A)
\]
Response (turnout) time of the system is a function of amount computation to be performed by each processor and the computation time. This function is defined by considering the processor with the heaviest aggregate computation and communication load. Response time of the system for a given allocation $A$ is defined by the following equation as:

$$ RT(A) = \max_{1 \leq j \leq n} \{ PEC(j) + IPCC(j) \} $$

Thus, the objective function for the response time of the system is expressed as:

$$ \text{Min } Z = \min \{ RT(A) \} $$

subject to

$$ \sum_{j=1}^{m} x_{i,j} = 1 \quad \text{for all } i = 1, 2, 3, \ldots, m. $$

$$ \sum_{i=1}^{m} e_{i,j} x_{i,j} \leq 1 \quad \text{for all } j = 1, 2, 3, \ldots, n. $$

where

$$ x_{i,j} = \begin{cases} 1, & \text{if } i^\text{th} \text{ module is assigned to } j^\text{th} \text{ processor} \\ 0, & \text{otherwise} \end{cases} $$

Processor Utilization: The main purpose of module allocation in a DCS is to reduce turnout time the system. This is done by maximizing the utilization of processors while minimizing the communication among processing nodes. While minimizing inter module communication tends to assign the whole modules to a single processing node, load balancing tries to distribute the program modules of a program almost evenly among the processing nodes. The utilization of each processor is calculated as:

$$ PU(j) = \frac{PEC(j)}{\max \{ PEC(j) : j = 1 \text{ to } n \} } $$

and the average processor utilization (APU) is calculated as:

$$ APU = \frac{[PU(1) + PU(2) + \ldots + PU(n)]}{n} $$

Processor’s Reliability: Reliability is defined in terms of the time interval in contrast to an instance in time defined in availability. A highly reliable system is one that will continue working for a long period of time. In DCS both system cost and system reliability are time dependent. Each component in DCS has two states: operational and failed. Reliability of the DCS is defined as the probability that the modules of the program can run successfully on the components (i.e. processors and communication link) during the time interval $[0, t]$ under an allocation $A$. Using the Poisson distribution, the execution reliability of the $k^{\text{th}}$ processor under the allocation $A$ is calculated as:

$$ ER(P_k) = \exp[- \lambda_k * PEC(k)] $$

Centre for Info Bio Technology (CIBTech)
Research Article

Where, $\lambda_k$ is the failure rate of the $k^{th}$ processor $P_k$.

The communication link reliability for $k^{th}$ processor, $P_k$ during an allocation $A$ is calculated as:

$$CLR(P_k) = \prod_{j=1}^{m} \exp\left[-\mu_{k,A(j)} \sum_{1 \leq i \leq m, A(i)=k \neq A(j)} c_{i,j} d_{k,A(j)}\right]$$

Where, $\mu_{k,A(j)}$ is the failure rate of link $l_{k,A(j)}$

The total communication reliability for $k^{th}$ processor, $P_k$ for an allocation $A$ and calculated as:

$$TCR(P_k) = ER(P_k) \times CLR(P_k)$$

Assumptions: To keep the algorithm reasonable in size several assumptions have been made while designing the algorithm. These assumptions are as:

i. A program is assumed to be collection of $m$-modules to be executed on a set of $n$-processors having different processing speeds and failure rates.

ii. A module may be portion of an executable code or data file. The number of modules to be allocated is more than the number of processors ($m >> n$), as normally in the case of real life.

iii. A module may take different execution time if it executes on different processor and amount of data may take different communication time if it is transmitted through the different communication links. Therefore, the system cost and system reliability both depend upon the execution and communication costs. If a module is not executable on any of the processor due to absence of some resources, the execution cost of that module on that processor is taken to be infinite.

iv. We assume that once a module has completed its execution on a processor, the processor stores the output data of the module in its local memory. If the data is needed by some other module being computed on the same processor, it reads the data from the local memory.

v. Whenever a group of modules is assigned to the same processors, the inter module communication cost between them is zero.

Scheduling Algorithm

In this section, we propose a heuristic modules algorithm for solving a load balancing modules allocation problem. The model addressed in this paper differs from previous work on module allocation as it finds:

a) Balanced allocated load on each processor.

b) Minimum response time of the system.

c) Minimum total communication cost.

d) Maximum reliability for the system.

The module scheduling scheme that we are presenting here has following major steps:

1) Calculation of inter-module communication costs.

2) Cluster making

3) Scheduling of the clusters to the processors.

4) Calculation of the costs and reliabilities.

The Inter-processor cost (IPC) is incurred due to the inter-module communication when the data are transferred from module to module if they are residing on different processors. Therefore, IPC is proportional to IMCC. IMCC is a function of data communication between the modules, data transfer rates between the processors and communication start-up costs of processors and calculated as:

$$c_{i,j} = \begin{cases} \alpha + \frac{data_{i,j}}{\beta}, & \text{if } i \neq j \\ 0, & \text{if } i = j \end{cases}$$
Modules are clustered based on their communication requirement. Highly communicating modules are clustered together to reduce communication delays. Usually, number of module clusters should be equal to the number of processors so that one to one mapping may result. These clusters will be fixed throughout their execution. Since we have 'n' number of processors in DCS, therefore, we will make 'n' number of module clusters. If a cluster resulting from combining modules becomes too large, it would be impossible to obtain a load-balanced scheduling therefore we restrict the number of modules in a cluster by:

Maximum number of modules in a cluster ≤ t+1

Where,

\[
t = \begin{cases} 
  \left\lfloor \frac{m}{n} \right\rfloor, & \text{if } \frac{m}{n} \text{ is an integer} \\
  \left\lfloor \frac{m}{n} \right\rfloor, & \text{otherwise} 
\end{cases}
\]

The inter-processor distance \(d_{x,y}\) between two processors \(p_x\) and \(p_y\) play an important role in total cost of the system as inter-processor communication cost varies linearly as distance \(d_{x,y}\) increases. We are taking this effect into account and map the module clusters to the processors. One concern in modules cluster mapping is that each processor has a roughly equal workload. For this we are changing cluster mapping to computing processor dynamically during the computation. Tie-breaking in selection of the processor is done randomly; i.e. one of the modules with equal cost is selected at random.

There can be alternative policies for tie-breaking but this kind of policy increases the time complexity of the algorithm, so we prefer a random selection strategy. The procedure of clustering the modules and their scheduling to the processors is described by the algorithm as:

\textbf{Algorithm:}

1. (a) Input: \( DT = [data_{i,j}] \), \( ECM = [e_{i,j}] \), \( DTR = [r_{i,j}] \)
\( IPDM = [d_{i,j}] \), \( L = [L_j] \), \( \lambda_j \), \( CFRM = [\mu_{j,l}] \).

   (b) Compute \( \alpha = \frac{\sum_{1 \leq j \leq n} L_j}{n} \) ← Average Communication start-up time of the processors.

   (c) Compute \( \beta = \frac{\sum_{1 \leq i \leq n} \sum_{1 \leq j \leq n} r_{i,j}}{n(n-1)} \) ← Average Data Transfer Rate.

2. (a) Compute \( t \).

   (b) Compute \( S_i = \sum_{1 \leq j \leq m} c_{i,j} \) for \( i = 1 \) to \( m \).

   (c) Find maximum of \( S_i \), if maximum of \( S_i \) is for \( i=k \), \( 1 \leq k \leq m \), then select \( \{c_i\} \) say \( \{c_{k1}, c_{k2}, \ldots\} \).

3. (a) Calculate new execution cost matrix \( NECM = [a_{i,j}] \) by adding rows corresponding to the modules present in the cluster \( C_i = \{M_k, M_l, M_m, \ldots\} \).

(b) Calculate new inter module communication cost matrix \( NIMCCM = [b_{i,j}] \) by adding row and column modules present in cluster \( C_i = \{M_k, M_l, M_m, \ldots\} \).
(c) Assign the cluster $C_i$ to that processor $P_j$ for which the cost is minimum say for $j=r$. If there is tie in selection, do it randomly.

4. Compute $\text{Cost}(C_i) = \text{Cost}\{M_{k_1}, M_{k_2}, \ldots\} = a_{k,r}$.

5. (a) Select the $k^{th}$ column $[b_{i,k}]^T$ of NIMCCM = $[b_{i,j}]$.
   (b) Calculate $d_{i,j}*[b_{i,k}] = [d_{r,j} * b_{i,k}]^T$.

6. (a) Modify the cost of NECM = $[a_{i,j}]$ by adding the column $[d_{r,j} * b_{i,k}]^T$ to the $j^{th}$ column of NECM = $[a_{i,j}]$ for $j = 1$ to $n$.
   (b) Reduce NECM = $[a_{i,j}]$ and NIMCCM = $[b_{i,j}]$ by removing rows and columns of $C_1$.

7. (a) Repeat step 2 to 3 for reduced NECM and NIMCCM to make the next cluster.
   (b) Assign the next cluster to that processor $P_j$ for which the cost is minimum say for $j = 1$ and $1 \neq r$.

8. Repeat step 4 to step 7.

9. If $n$ cluster are assigned to ‘$n$’ processor then go to step 10 else go to step 8.

10. Compute:

(a) $\text{TCOST}(j) = \text{PEC}(j) + \text{IPCC}(j)$

(b) $\text{PU}(j) = \frac{\text{PEC}(j)}{\max\{\text{PEC}(j) : j = 1 \text{ to } n\}}$

(c) $\text{TCR}(P_k) = \text{ER}(P_k) * \text{CLR}(P_k)$

11. Compute:

(a) $\text{RT}(A) = \max\{\text{PEC}(j) + \text{IPCC}(j)\}_{i \leq j \leq n}$

(b) $\text{TCOST}(A) = \text{EC}(A) + \text{TCC}(A)$

(c) $\text{APU} = [\text{PU}(1) + \text{PU}(2) + \ldots + \text{PU}(n)]/n$

(d) Compute Total Reliability $= \prod_{k=1}^{n} \text{TCR}(p_k)$

12. End.

RESULTS AND DISCUSSION
Load balancing modules allocation model for heterogeneous processors was discussed in the previous section. To evaluate our proposed model we use a different size of problem in this section. In experimental problem we have consider a distributed program made up of five modules $\{M_1, M_2, M_3, M_4, M_5\}$ to be executed on a set of three heterogeneous processors $\{P_1, P_2, P_3\}$. The failure rates and communication start up time of processors $P_1, P_2, P_3$ are 0.00002, 0.00001, 0.00003 units and 3, 2, 4 units respectively. The various matrices taken as input are described in tables-1 to table-4.

For evaluating the performance of our algorithm a large number of programs were considered. With these applications, simulation experiments were carried out. The execution costs of the modules were picked randomly in the interval from 5 to 100, and inter-module communication costs were chosen in such a way that the range lies from 1 to 20, that is execution costs were selected approximately 2-30 times larger than the inter-module communication costs. The numbers of modules in the examples were restricted to twenty. These programs were tested on Yadav et al., (2011) and present model. It is found that in 78% cases the present model gives better results as comparative to Yadav et al., (2011). In 17% cases, the obtained results are equal and there are only 5% cases where the present model gives worse results as comparative to Yadav et al., (2011). The algorithm suggested in Richard et al., (1982) is not considered the criteria of load balancing and proper utilization of each processor whereas our model considered both the issues. The run time complexity of the algorithm suggested by Richard et al., (1982) is O(mn) which to very high. The algorithm suggested by Sagar and Sarje (1991) has run time complexity O(m^2n). The run time complexity of the algorithm presented in this paper is O (m^2+mn) which is less than the complexities of the models (Richard et al., 1982; Sagar and Sarje, 1991).
